Randomized Trial

Effectiveness of Exercise Therapy and Manipulation on Sacroiliac Joint Dysfunction: A Randomized Controlled Trial

Parisa Nejati, MD, Afsaneh Safarcherati, MD, and Farshid Karimi, MD

Background: The sacroiliac joint dysfunction (SIJD) has been found to be the primary culprit for lower back pain (LBP), but it is still overlooked and treated as LBP. There are no guidelines or appropriate therapeutic protocols for SIJD. Thus, there is a need for an effective treatment strategy for SIJD.

Objective: To compare exercise therapy (ET), manipulation therapy (MT), and a combination of the 2 (EMT) in terms of their effectiveness in treating SIJD.

Study Design: A comparative, prospective, single-blind randomized controlled trial.

Setting: Sports Medicine Department of Rasoul Akram Hospital.

Methods: A total of 51 patients with lower back or buttock pain resulting from SIJD were randomly assigned to 1 of 3 study groups: ET, MT, or EMT. The ET group received posterior innominate self-mobilization, sacroiliac joint stretching, and spinal stabilization exercises. The MT group underwent posterior innominate mobilization and SIJ manipulation. Lastly, the EMT group received manipulation maneuvers followed by exercise therapy. Pain and disability were assessed at 6, 12, and 24 weeks after the interventions.

Results: All 3 groups demonstrated significant improvement in pain and disability scores compared to the baseline (P < 0.05). The difference among these therapeutic protocols was found to be a function of time. At week 6, MT showed notable results, but at week 12, the effect of ET was remarkable. Finally, at week 24, no significant difference was observed among the study groups.

Limitations: A major limitation of the present study is lack of a control group receiving a type of intervention other than the experimental protocols. Another limitation is the short duration of follow-ups.

Conclusions: Exercise and manipulation therapy appear to be effective in reducing pain and disability in patients with SIJD. However, the combination of these 2 therapies does not seem to bring about significantly better therapeutic results than either approach implemented separately.

Key words: Exercise therapy, manipulation therapy, sacroiliac joint dysfunction

Sacroiliac joint dysfunction (SIJD) is pain in the lower back caused by alteration in the normal joint motion ascribable to hypomobility or hypermobility (1). SIJD has been found to be the primary cause of lower back pain (LBP) in 15 to 40% of patients (2-6). Pain in the sacroiliac joint (SIJ) region can additionally cause groin and thigh pain. Tenderness in the SIJ upon palpation is a reliable sign that the SIJ is the source of pain (6). SIJ functionality is affected by different pathological changes, the commonest of which seem to be related to biomechanical inefficiencies (7).
Standard physical therapy interventions can be employed to correct the underlying pathology and to alleviate the symptoms in SIJD. Such interventions include repetitive exercises, manual joint mobilization, manipulation, sacroiliac belts, massage, patient education, aerobic conditioning, and electrotherapeutic modalities (6,8-9).

Although exercise therapy is provided as a valuable method in LBP treatment (10-14), few studies have been concerned with the efficacy of this option in SIJD. Moreover, manipulation has some therapeutic effects such as stretching of the soft tissues around the joint, improving range of motion, reducing edema and muscle spasm, correcting joint defects, and controlling pain (15,16).

In spite of the high prevalence of SIJD, there are no guidelines or appropriate therapeutic protocols for this syndrome. Physicians usually refer to it as LBP only. Indeed, SIJD is still overlooked as a potential contributor to LBP. Furthermore, only a few studies have sought to compare the effectiveness of different therapeutic modalities (6,17). This motivated us to evaluate supportive care by comparing the effects of exercise therapy and manual joint mobilization on pain intensity and disability in patients with SIJD in Iran. Moreover, this trial aimed to provide a more detailed insight into the short- and long-term effects of the 3 treatment choices under investigation on the clinical features of SIJD.

**METHODS**

This study was conducted as a single-blind randomized controlled trial (i.e., where the data analyzer was blind to the study) with 6-, 12-, and 24-week follow-ups in the Sports Medicine Department of Rasoul Akram Hospital in Tehran during the period spanning December 2013 to February 2016. Patients with LBP were recruited from musculoskeletal clinics of Rasoul Akram Hospital. The patients who met the following criteria were included in the study: LBP or buttock pain lasting for at least 3 months, age over 20 years, no history of spine and hip surgery in the year prior to the study, no pregnancy, no osteoporosis (T-score < 2.5 in bone densitometry) or bone fractures, no pain radiating below the knees, not receiving physical therapy in the lower back and buttocks over the preceding 3 months, non-injection of corticosteroids or anesthetics in the SIJ during the previous month, absence of sacroiliitis or sacroiliac infection, and testing positive in at least 3 of the following:

- Gaenslen’s Test
- Standing Forward Bending Test
- Patrick’s Test
- Gillet Test
- Yeoman’s Test
- Thigh Trust Test and other sacroiliac tests.

The participants were excluded if they had intensified pain, were involved in other treatments for pain relief, and discontinued the intervention protocol for any reason.

The 56 eligible patients were divided into 3 groups. The written informed consent of all the patients was obtained prior to inclusion in the study. The computer-generated randomization was applied by a staff member blind to the study. Of the total number of eligible patients, 19 were allocated to the “exercise therapy” (ET) group, 18 to the “manipulation therapy” (MT) group, and 19 to the “exercise plus manipulation therapy” (EMT) group. All the patients were requested not to receive other treatments for 24 weeks.

**Study Protocol**

The patients in the ET group were instructed by a sports medicine specialist how to perform the exercises at home on a daily basis. They were also asked to visit the hospital once a week until week 12 for supervised exercises. After that, they did not perform exercises until week 24. The exercises were posterior innominate self-mobilization, sacroiliac joint stretching, and spinal stabilization. A brief description of each exercise follows.

1) **Self-mobilization Exercises**

Posterior innominate self-mobilization was done in a supine position. The patient grasped behind the flexed knee and gently moved it toward the trunk. This exercise rocked the innominate in a posterior direction.

2) **Sacroiliac Joint Stretches**

These exercises were performed in both right side-lying and left side-lying positions. The patient was in the side-lying position, with the upper hip being flexed 70 to 80 degrees and the knee flexed about 90 degrees. The patient’s trunk was then rotated toward the upper side as far as was comfortable. The patient was instructed to lift the top leg into hip abduction and internal rotation and resist the researcher or the partner for 5 seconds. The patient was instructed to breathe and exhale as the trainer gently over-pressured the trunk rotation. The patient was then instructed to relax the hip and leg and allow the leg to drop toward the floor. As the patient relaxed, a gentle overpressure was applied...
to the foot as the patient was allowing the hip and leg to drop further to the floor. This exercise was done 5 times a day with 2 minutes of rest between the sequences.

3) Spinal Stabilization Exercises

These exercises were in four phases. Each new phase began every three weeks.

**Phase 1**
- Supine abdominal draw-in
- Abdominal draw-in, with one knee drawn to the chest
- Abdominal draw-in, with the heels sliding backward one after the other
- Abdominal draw-in, with both knees drawn to the chest
- Supine twist
- Prone bridging on elbows
- Side bridging on elbows
- Prone cobra
- Quadruped opposite arm-leg lift

**Phase 2**
- Abdominal draw-in with feet on the medicine ball plus abdominal draw-in with feet on the ball and added movement
- Prone bridging on elbows with single-leg hip extension
- Quadruped opposite arm-leg lifts, with cuff or dumbbell weights

**Phase 3**
- Prone bridging, with the feet on the ball
- Side bridging with single-leg hip abduction
- Quadruped opposite arm-leg lifts on “half foam rollers”
- Twisting while seated on medicine ball

**Phase 4**
The exercises in Phase 4 were performed dynamically, meaning that the therapist threw a soccer ball-size medicine ball to the patient who was trying to stay in the position pertinent to the exercises in Phase 3.

It should be noted here that each exercise was to be repeated 10 times a day.

In the MT group, 2 manual maneuvers of posterior innominate rotation were implemented: i.e., posterior innominate mobilization and SIJ manipulation as shown in Figs. 1 and 2, respectively. It is to be noted that the former is low-velocity and low-amplitude, while the latter is high-velocity and low-amplitude. The maneuvers were performed in the first...
session by the sports medicine specialist with 8 years of experience in manipulation. Immediately afterward, the Standing Forward Bending Test (18) and Gillet Test (19) were administered, with the negative results indicating the effectiveness of the manipulation for rotating innominate posteriorly. In the case of positive results, both maneuvers were repeated immediately, and then the aforementioned tests were administered again. If the test results were still positive, the respective patients were excluded. The patients testing negative were asked to refer back to the therapist at the designated follow-up times.

In the EMT group, first the manipulation maneuvers depicted in Figs. 1 and 2 were performed. If these maneuvers proved effective, the exercises for the ET group were taught to the patients, who were asked to do the prescribed exercises at home on a daily basis. They were additionally requested to visit the hospital once a week until week 12 to receive supervised exercises. Following this period, they were asked to only perform unsupervised home-based exercises until week 24.

Outcome Measures

The outcomes were pain and functionality. These were evaluated both subjectively and objectively before the treatment and at 6, 12, and 24 weeks. Subjectively, pain was evaluated using the Visual Analog Scale (VAS), and functionality was assessed using the Oswestry Disability Index (ODI) and the Roland-Morris Back Pain Questionnaire. The reliability and validity of the Persian version of the functionality questionnaires has been confirmed in the literature (20). Functionality was also objectively evaluated via the “timed up and go” and “self-paced walk” tests (21).

Statistical Analysis

Data analysis was performed using SPSS 23 (IBM Corporation, NY, USA, 2015). The normality of the distribution of the continuous variables was determined using the Shapiro-Wilk test. The data pertinent to these variables are shown as either mean ± SD or median, as appropriate. The categorical variables were analyzed using the chi-squared test. Pretreatment differences among the 3 groups were determined using ANOVA. Repeated-measures analysis was used for evaluating the time effect in the follow-ups. To determine the treatment effect, the data were analyzed using either a random effects mixed model or a generalized estimating equations model, as appropriate. The Tukey’s test was used for pairwise comparisons of the study groups.

To assess the intra-tester reliability of objective tests, 10 healthy subjects had repeated measurements 7 days apart in a pilot study. The test-retest reliability of the “timed up and go” and “self-paced walk” tests was assessed using interclass correlation coefficients (ICC) at the 95% confidence level. The ICCs between the first and second measurements were 0.90 and 0.95 for “timed up and go” and “self-paced walk” tests, respectively.

For all tests, statistical significance was set at an α level of < 0.05 (2-tailed).

Results

Of the 56 patients who met the inclusion criteria, 51 patients were subjected to the final assessment, equaling a dropout of about 9%. More particularly, 2 patients in the ET group were excluded because of their irregular visits and failure to do home-based exercises at weeks 12 and 24. In addition, 1 patient in the MT group refused to complete the study protocol due to the disappearance of pain. Finally, 2 patients in the EMT group preferred to try other treatments since there was no improvement in their pain. Therefore, ultimately 17 patients remained in each group for analysis (Fig. 3).

Of the 51 patients being analyzed, 12 (23.5%) were men and 39 (57.6%) women. Gender distribution was not significantly different from 1 group to another (P = 0.28).

The mean age of the patients was 46.8 years (ranging 23-60 years). There was no statistically significant difference in age distribution among the 3 groups (P = 0.22).

The mean weight of the participants ranged from 51 to 98 kg. No significant differences were noted in weight distribution between the study groups (P = 0.84).

Following the classification developed by the American College of Sports Medicine, a moderate physical activity of less than 90 minutes per week was determined as an activity factor of less than 1.5 (22). Sixty-two percent of the patients had this rating. In terms of physical activity, the statistical difference among the 3 groups did not reach significance (P = 0.76).

Table 1 presents the time effect of the 3 interventional methods. For all groups, the subjective measures showed significant improvement in each follow-up compared to the baseline (P < 0.001). However, the objective measures revealed dramatic improvement only until week 12.
Table 2 compares the study groups in terms of the outcome parameters measured at 4 points in time. As the table shows, except for the ODI, there was no statistically significant difference among the 3 methods at baseline. At week 6, MT showed a higher score than the other two methods, and at week 12, ET yielded better results. However, at week 24, there was no significant difference among the 3 methods.

**The Tukey’s Pairwise Analysis Results**

**ET vs. MT**

All the outcomes in the MT group were better than in the ET group at week 6. However, at weeks 12 and 24, ET was as effective as MT in two of the parameters (i.e., the objective functional tests) ($P < 0.001$) and more effective in terms of the other parameters ($P = 0.024$).
Table 1. The time effect of the 3 interventional methods as demonstrated by the outcome measures of the study.

**ET vs. EMT**

No significant difference was observed between the ET and EMT groups in all measures at weeks 12 and 24 ($P > 0.05$). However, at week 6, EMT proved more efficient than ET in subjective tests, VAS, and the objective test of “timed up and go” ($P = 0.032$).

**MT vs. EMT**

Adding exercise therapy to manipulation did not reduce the intensity of pain ($P = 0.123$). However, the EMT group produced better results than the MT group in terms of Roland-Morris score at weeks 4 and 12 ($P = 0.024$), ODI at weeks 4 and 24 ($P = 0.023$), and functionality objective tests at weeks 12 and 24 ($P < 0.001$).

**Discussion**

To the best of our knowledge, this work is one of the first studies comparing different therapeutic modalities for SIJD in Iran. The results showed that all the 3 methods (i.e., ET, MT, and EMT) can reduce pain and disability compared to the baseline. It is noteworthy that this positive effect persisted for 24 weeks in the subjective tests and for 12 weeks in the objective tests although the results from the objective tests are more valid to the researchers. A possible explanation for the more enduring results of the subjective tests is that a rewarding experience with the tests made the patients answer the questions favorably.
At week 6, MT yielded better results than ET in terms of pain relief, showing the quicker positive effect of the former. This could be due to its analgesic effect, either from structural (23-25) or neurological processes (26,27). Another plausible explanation is the antispasmodic effect of manipulation as confirmed by Orakifard et al (15). The quick onset of MT results in this study echoes the findings of Kristin and colleagues (28), who demonstrated the positive role of 4 manual high-velocity and low-amplitude techniques in reducing pain and disability in patients with SJJD over a period of 2 weeks. A previous study of the authors of this study (16) showed that 2 high-velocity and low-amplitude techniques of posterior innominate rotation followed by daily low-velocity and low-amplitude self-mobilization techniques for 1 month could improve pain and functionality in the patients with SJJD.

In line with the present study, Hidalgo’s (29) systematic review demonstrated moderate to strong evidence supporting the greater utility of manipulation compared to sham treatment in controlling chronic non-specific LBP in the short run. Similarly, another systematic review, by Ruddock (30), supported the positive effect of spinal manipulation on chronic non-specific LBP compared to sham therapy. On the other hand, another systematic review by Assendelft et al (31), suggests that manipulation is not particularly more beneficial than other conventional methods like exercise therapy, needling, and analgesics in treating chronic LBP; however, this later review suggests that manipulation is more effective in controlling pain in acute LBP.

In a review of the studies into the effect of manipulation on acute LBP, Chaitow (32) approves of the findings of Assendelft et al’s (31) study and argues that it is not reasonable to dismiss spinal manipulation as a clinical treatment option for acute LBP.

In our study, after week 6, MT was not superior to ET in treating chronic LBP, and indeed it was less effective. The possible reason why MT was more effective at week 6 was explained above.

At week 12, ET showed better outcome than the other treatment modalities, confirming that ET takes more time to begin to be effective because neuromuscular adaptation in muscles needs at least 6 weeks to take place (23).

At week 24, there was no significant difference among the 3 treatment groups. This could be attributed to the fact that the effect of ET declined in the interval between week 12 and week 24, when the patients did not perform any exercise. Indeed, the sustainability of the effect of prescribed exercises depends on their continuity.

A systematic review conducted by Standaert et al (33) concluded that although various methods are used, there is hardly any evidence to support that exercise therapy and manipulation are equally effective in reducing chronic LBP and improving performance.

Given the positive effect of ET and MT when implemented alone, we expected that a combination of these 2 modalities would be more effective. However, we observed that EMT results were better than the outcome brought about by ET only at week 6. This is because, as already discussed, the positive effect of MT appears at week 6, but the effect of ET needs more time to appear. In other words, MT adds no extra positive effect to that of ET after week 6. However, Hidalgo’s review (29) reported moderate evidence for the effectiveness of EMT compared to ET in terms of pain relief, improvement in functionality, and quality of life in both the short run and the long run.

As for the comparison between MT and EMT, contrary to our expectation, the EMT group did not outperform the MT group at week 6 in any of the measures. A plausible explanation for this could be that the patients in the EMT group, who received ET after MT, were not so motivated to perform ET due to the faster pain relief emanating from MT. However, at week 12, EMT yielded significantly better results than MT in all measures. Moreover, at week 24, there was no difference between MT and EMT because, as previously stated, between weeks 12 and 24, the subjects did not keep to any of the therapeutic protocols.

A comparison between the ET, MT, and EMT groups in UK BEAM (United Kingdom back pain exercise and manipulation) trial team’s study (34) showed that the patients receiving exercise therapy benefited little at month 3, and nothing at month 12; those in the manipulation group gained little to moderate advantage at month 3, and little at month 12; and finally the patients who received both exercise therapy and manipulation improved moderately at month 3, and little at month 12. According to that study, manipulation yielded better results in chronic LBP, and the authors also found that in most parameters evaluating pain and disability (i.e., Roland disability, Von Korff pain score, SF-36, and fear avoidance beliefs), the most satisfying results were observed at month 3, but those results did not persist until month 12. These findings are in line with the results of the present study.
It is to be noted at this juncture that the bulk of the past research seems to have been concerned with the effect of ET on LBP (13,35-42) rather than on SJD. With this in mind, the authors hope that the present study could be a trigger for more research into this syndrome.

Limitations
A major limitation of the present study is lack of a control group receiving a type of intervention other than the experimental protocols. Another limitation is the short duration of follow-ups.

Conclusion
The present study was aimed at comparing ET, MT, and EMT in terms of their effectiveness in treating SJD. All 3 treatment options succeeded in relieving pain and improving functionality for a period of 24 weeks compared to baseline. Furthermore, the therapeutic effect of MT appeared more quickly (at week 6), but ET proved more effective in improving functionality at week 12. In addition, no significant difference was observed between ET, MT, and EMT after 6 weeks. Overall, it can be concluded that manipulation can be an effective approach to reducing pain in the SIJ.

Suggestions
In the present study, we examined the combined effect of self-mobilization, SIJ stretching, and spinal stabilization exercises on the alleviation of SJD symptoms. A possible avenue of research would be to study the role of exercise type in reducing pain and disability and to draw a comparison among these exercises. Additionally, it would be interesting to evaluate the long-term effects of different therapeutic methods.
